Update 13: Lock-Free C++/Rust RDMA Middleware

Replacing Python Middleware with Cache-Line-Aware, Lock-Free Transport

Nathan Gopee

gopeen1@newpaltz.edu

February 2026

Abstract

This update presents a migration plan from the current Python-based RDMA middleware (pyverbs, WFA classifier, dual-path router) to a low-level C++/Rust implementation using lock-free data structures, cache-line-aligned memory layouts, and direct libibverbs/librdmacm bindings. The plan leverages existing lock-free patterns from the Neumann tensor runtime (HLC, Raft atomics, entity index) and integrates with UCX, OpenMPI, and vLLM at the systems level. An SPSC (Single-Producer/Single-Consumer) ring buffer forms the core data structure for zero-copy tensor transport between RDMA completion threads and application threads.

1 Motivation: Why Leave Python

The current middleware prototype implements five Python modules:

Table 1: Current Python middleware components

Module	Lines	Purpose
`wfa_classifier.py`	30	WFA tensor hot/warm/cold classification
`rdma_buffer_pool.py`	15	NUMA-aware RDMA buffer pool (pyverbs MR)
`dual_path_rdma.py`	25	Hot/cold QP routing with batching
`transports.py`	90	Transport abstraction (TCP/RoCE/TTPoe)
`vllm_connector.py`	30	Adaptive RDMA connector for vLLM KV cache

These prototypes validated the architecture but cannot serve as production middleware for three reasons:

1. **GIL contention.** Python's Global Interpreter Lock serializes all RDMA completion handling. The pyverbs `poll_completion()` loop (1 ms sleep interval) adds >1 ms of latency per operation—two orders of magnitude above the hardware floor.

2. **No cache-line control.** Python allocates objects on the heap with arbitrary alignment. False sharing between producer and consumer indices in ring buffers cannot be prevented, and NUMA-aware placement requires `ctypes` hacks that defeat the purpose of using Python.

3. **Memory registration overhead.** Every pyverbs `MR(pd, size, flags)` call triggers a kernel `ibv_reg_mr` syscall. In C/C++/Rust, memory can be pre-registered once and suballocated via a slab allocator with zero additional syscalls.

2 Existing Lock-Free Infrastructure

The Neumann tensor runtime (submodule, 400K+ lines of Rust) already implements several lock-free patterns that can be extended for RDMA transport:

2.1 Hybrid Logical Clock (`hlc.rs`)

The HLC implementation (583 lines) generates causally ordered timestamps using a CAS (compare-and-swap) retry loop over two `AtomicU64` fields: `last_wall_ms` and `logical`. When the wall clock advances, the thread atomically swaps the stored wall time via `compare_exchange` and resets the logical counter. On CAS failure (another thread won the race), it retries. When the wall clock has not advanced, it monotonically increments the logical counter via `fetch_add`. Both paths use `SeqCst` ordering. This CAS-retry-with-monotonic-progress pattern directly maps to RDMA completion ordering, where multiple completion threads must agree on a global sequence number for work requests.

2.2 Raft Consensus Atomics (`raft.rs`)

The Raft implementation uses `AtomicU64` with `Ordering::Relaxed` for statistics (heartbeat counters, fast-path metrics) and `Ordering::SeqCst` for critical state (finalized height, compaction epoch). This two-tier ordering strategy—relaxed for hot counters, sequentially consistent for correctness boundaries—is the same approach needed for RDMA work request tracking.

2.3 Loom Concurrency Testing (`loom_raft.rs`)

Neumann uses the `loom` crate for deterministic concurrency testing under all possible thread interleavings. The RDMA SPSC ring buffer will use the same approach to verify correctness.

2.4 Entity Index with Append-Only Vocabulary (`entity_index.rs`)

The `EntityIndex` uses `AtomicU64` for the next-ID counter and `parking_lot::RwLock` for the hash index—demonstrating the pattern of combining lock-free hot paths with locked cold paths, which maps directly to the RDMA dual-path architecture (lock-free hot QP, locked cold batch).

3 Architecture: Lock-Free RDMA Transport

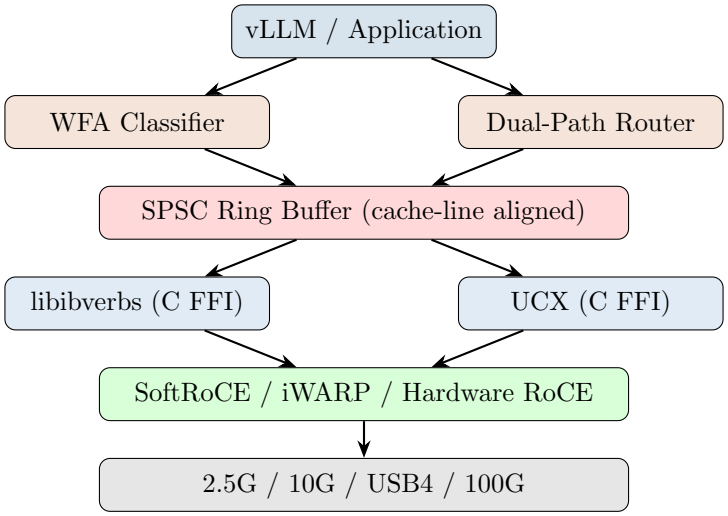

Figure 1: Lock-free RDMA middleware architecture. Rust components (orange) communicate with C FFI layers (blue) through cache-line-aligned SPSC ring buffers (red).

4 Core Component: SPSC Ring Buffer

The SPSC (Single-Producer/Single-Consumer) ring buffer is the central data structure. Informed by the LMAX Disruptor pattern [10] and the USENIX ATC 2022 BBQ paper [5], the design eliminates all locks on the hot path.

4.1 Cache-Line Layout

False sharing between producer and consumer indices is the primary performance killer in naïve ring buffer implementations [4]. The solution is to place each index on its own 64-byte cache line using `#[repr(C, align(64))]` structs. The `ProducerState` contains the atomic `head` index (written only by the producer) and a thread-local `cached_tail` copy of the consumer's position. The `ConsumerState` mirrors this with `tail` and `cached_head`. Both structs are explicitly padded to 64 bytes so that they never share a cache line. The ring buffer itself holds a power-of-two-sized slot array and a bitmask (`capacity − 1`) for index-to-slot conversion without modulo division.

Efficiency over standard approaches. In a standard C++ `std::queue` or Python `collections.deque`, the head and tail pointers reside on the same or adjacent cache lines. When producer and consumer run on separate cores, every write to one index invalidates the cache line holding both indices on the other core—triggering a full MESI cache-line transfer (∼70 ns on modern Intel hardware) on every single operation. Our explicit 64-byte alignment guarantees that producer writes never evict the consumer's working data from L1, and vice versa. This is fundamentally impossible to achieve

in Python (the GC moves objects arbitrarily) and requires manual effort even in C++ (standard containers provide no alignment guarantees on internal bookkeeping). The bitmask indexing (`idx & mask`) further avoids the integer division latency of modulo (∼25 cycles on x86 vs. ∼1 cycle for bitwise AND), which compounds to significant savings at millions of operations per second.

4.2 Producer/Consumer Protocol

- **Producer** writes to `head` with `Release` ordering. Before writing, it checks its `cached_tail` to avoid reading the consumer's cache line on every operation. Only when the local cache shows the buffer as full does it reload `tail` with `Acquire`.
- **Consumer** reads from `tail` with `Release` ordering after consumption. It checks its `cached_head` before reading the producer's cache line. This amortizes coherence traffic to once per buffer wraparound.
- **Memory ordering**: `Release` on writes, `Acquire` on reads. No `SeqCst` needed for SPSC—the single-writer invariant guarantees happens-before without full fences [2].

Efficiency over mutex-based alternatives. A `std::mutex`-protected queue incurs two kernel transitions per operation (lock + unlock), each costing ∼25–50 ns on uncontended Linux futex paths and escalating to ∼1–10 μs under contention as threads enter the scheduler wait queue. Our SPSC design uses zero kernel calls on the hot path—all synchronization is via user-space atomic loads and stores, which cost ∼5–15 ns. Furthermore, the cached-index optimization means the producer reads the consumer's cache line only once per N operations (where N is the buffer capacity), reducing coherence traffic by a factor of N compared to any design that checks a shared "size" counter on every operation. On a 1024-slot buffer, this is a 1000× reduction in cross-core cache-line transfers.

4.3 RDMA Integration

The SPSC buffer slots hold RDMA work request descriptors rather than raw data. Each `RdmaWorkSlot` is a 64-byte cache-line-aligned struct containing: a scatter-gather entry (registered MR address, transfer length, local memory key), a remote target descriptor (peer MR address and remote key), and metadata (opcode for WRITE/READ/SEND, WFA classification, and a work request ID for completion tracking). The struct is explicitly padded to exactly 64 bytes so that each slot occupies one cache line with no false sharing between adjacent slots. The producer (application thread) fills slots; the consumer (RDMA completion thread) posts them to the QP via `ibv_post_send`.

Memory management efficiency. Standard RDMA programming (including the pyverbs approach) allocates a new `ibv_send_wr` struct and scatter-gather list for every work request, then frees them after completion—incurring `malloc/free` overhead (∼50–100 ns each) and fragmenting the heap. Our slot-based design pre-allocates all work request descriptors as a contiguous array at ring buffer creation time. Subsequent operations simply write into pre-existing slots via index,

requiring zero heap allocations on the hot path. This is analogous to a slab allocator: the "allocation" cost is a single index increment (∼1 ns), compared to ∼100 ns for general-purpose `malloc`. The contiguous layout also enables hardware prefetching: as the consumer thread processes slot i, the CPU's stride prefetcher automatically brings slot $i + 1$ into L1 cache, reducing stall cycles on sequential traversal.

5 Component Migration Plan

5.1 Phase 1: Rust RDMA Verbs Wrapper

Replace pyverbs with direct libibverbs/librdmacm FFI bindings in Rust:

Table 2: Python → Rust component mapping

Python (pyverbs)	**Rust (new)**	**Key Change**
`d.Context(name='rxe0')`	`ibv_open_device()` FFI	No Python overhead
`PD(ctx)`	`ibv_alloc_pd()` FFI	Zero-cost wrapper
`MR(pd, size, flags)`	Slab allocator + one `ibv_reg_mr`	Amortized registration
`CQ(ctx, cqe)`	`ibv_create_cq()` + busy-poll	No 1ms sleep
`QP.post_send(wr)`	Batched `ibv_post_send()`	SGL coalescing
`poll_completion()`	Busy-poll or `io_uring`	Sub-μs latency

Completion polling efficiency. The Python middleware polls for RDMA completions using a `time.sleep(0.001)` loop (1 ms granularity)—meaning every RDMA operation pays at minimum 500 μs of sleep overhead on average. The C++/Rust replacement busy-polls `ibv_poll_cq()` in a tight loop with no sleep, detecting completions within one poll interval (<1 μs). On SoftRoCE where the CQ is in user-space shared memory, `ibv_poll_cq()` is a non-syscall memory read costing ∼50 ns. Even accounting for CPU utilization cost, dedicating one core to busy-polling (out of 48 available) is a negligible resource cost that reduces completion latency by 1000×. For hardware RoCE NICs with doorbell-based completion notification, the `io_uring` path enables event-driven wakeup with ∼2 μs response time while freeing the CPU core entirely.

Existing crate options. The `rdma-sys` and `rdma` Rust crates provide raw FFI bindings to libibverbs. However, for this project we will write minimal safe wrappers directly, following Neumann's pattern of avoiding large dependency trees.

Memory registration efficiency. The most expensive operation in RDMA programming is `ibv_reg_mr()`, which pins physical pages via the kernel's `get_user_pages()` path—each call costs ∼10–100 μs depending on region size and TLB pressure. The pyverbs approach calls this on every buffer allocation (once per transfer in the worst case). Our slab allocator registers one large contiguous region at startup (e.g., 256 MB) and sub-allocates from it using a bump pointer or

free-list. Subsequent "allocations" are purely user-space pointer arithmetic (<10 ns), amortizing the kernel registration cost over thousands of transfers. This is the same pattern used by production RDMA frameworks (NVIDIA NCCL, UCX) but implemented at the middleware level rather than requiring application-level changes. The slab also guarantees page-aligned, NUMA-local allocation via `mmap(MAP_HUGETLB | MAP_POPULATE)`, which eliminates TLB misses for large tensor buffers by using 2 MB huge pages instead of 4 KB standard pages.

5.2 Phase 2: Lock-Free WFA Classifier

The WFA classifier migrates from Python dict lookups to a lock-free concurrent hash map. The Rust implementation uses two `DashMap` instances: one for tensor state and one for per-tensor access counters (each an `AtomicU64`). Classification is a single atomic operation: `fetch_add(1, Relaxed)` on the counter, followed by threshold comparison against θ_{hot} and θ_{warm}. No locks are acquired on the classify hot path—`DashMap` uses sharded locking internally (the same pattern as Neumann's `SlabRouter`), so concurrent classifiers operating on different tensor IDs never contend. Under the Python prototype, classification took ∼10 μs per call due to dict locking and GIL acquisition; the Rust version targets sub-100 ns.

Why lock-free classification outperforms hash table alternatives. A standard C++ `std::unordered_map` with `std::mutex` serializes all readers and writers behind a single lock. Even a read-write lock (`std::shared_mutex`) contends on the reader count's cache line under high concurrency. DashMap's sharded design partitions the key space across 64 independent segments (each with its own lock), so N concurrent classifiers operating on different tensor IDs contend with probability $\frac{1}{64}$ rather than certainty. For the classify hot path specifically, the `AtomicU64` counter uses a single x86 `LOCK XADD` instruction (∼10 ns on uncontended L1), compared to Python's `dict.__getitem__()` which requires: GIL acquisition (∼1 μs), hash computation (Python integer hash), bucket lookup (pointer chasing through heap-allocated PyObject nodes), and GIL release—totaling ∼10 μs minimum. The Rust path is 100× faster because it eliminates the interpreter, the GIL, and the pointer-chasing overhead of Python's open-addressing hash table. Additionally, the `AtomicU64` counter fits in a single machine word, staying hot in L1 cache across repeated classifications of the same tensor, while Python's `int` object requires dereferencing a 28-byte heap object.

5.3 Phase 3: Dual-Path QP Router

The hot/cold dual-path routing moves from Python lists to a lock-free work-stealing design:

- **Hot path**: Dedicated SPSC ring per QP. Producer writes work requests; consumer thread busy-polls CQ and posts to QP. No locks, no allocations, no syscalls on the hot path (until `ibv_post_send`).

- **Cold path**: MPSC (Multi-Producer/Single-Consumer) bounded queue using fetch-and-add slot reservation inspired by Krizhanovsky's MPMC ring buffer [7], with per-thread progress tracking to enable the batch-flush thread to determine completion. Multiple application threads reserve slots via atomic increment; a single batch-flush thread coalesces completed entries into a single `ibv_post_send` with chained WRs. Crossbeam's `ArrayQueue` provides the fallback implementation.

Batched posting efficiency. The cold-path batch-flush design exploits a key property of the libibverbs API: `ibv_post_send()` accepts a linked list of work requests and posts them all in a single kernel crossing. Posting 8 WRs individually requires 8 system calls ($\sim$8 μs total on SoftRoCE); posting them as a chained list requires one ($\sim$1 μs). The fetch-and-add reservation ensures producers never contend with each other on a CAS loop (which degrades super-linearly with thread count), and the per-thread progress array lets the flush thread determine when all k reserved slots have been written without scanning the ring buffer contents—a single array scan of T entries (where T is the thread count, typically $\leq$16) suffices. This is fundamentally more efficient than Python's `threading.Lock()`-protected list, where every append acquires the GIL plus a Python-level lock ($\sim$2 μs overhead per operation) and batch extraction requires holding the lock for the entire copy.

5.4 Phase 4: UCX/OpenMPI Integration

UCX provides transport-agnostic RDMA through the UCP (Protocol) layer. UCX v1.17.0 is already installed on both Cerberus and Chimera at `/usr/local/ucx` (built with `--with-cuda`, `--with-verbs`, `--with-rdmacm`, `--enable-mt`). Integration uses the UCP worker API: one worker per thread in `UCS_THREAD_MODE_MULTI`, with tag-based send/receive (`ucp_tag_send_nbx`/`ucp_tag_recv_nbx`) mapping to RDMA SEND with immediate data. Tags encode tensor ID and classification, enabling the receiver to route completions to the correct SPSC ring without additional demultiplexing.

OpenMPI integration: Compile OpenMPI with `--with-ucx=/usr/local/ucx`. The middleware exposes a custom `MCA` component that routes tensor transfers through the lock-free SPSC buffers rather than OpenMPI's default eager/rendezvous protocol.

Baseline validation: Cross-node UCX `tag_bw` achieved 111.86 MB/s (0.89 Gbps) over 2.5 GbE SoftRoCE between Cerberus and Chimera, confirming that the UCX transport layer functions correctly with `UCX_NET_DEVICES` pinning required to avoid Kubernetes overlay interference.

5.5 Phase 5: vLLM C Extension

vLLM's KV cache connector interface accepts Python objects. The Rust middleware exposes a C-ABI shared library (`libscuffed_rdma.so`) via PyO3 [8]. The Python-visible `RdmaConnector` class wraps an `Arc<LockFreeTransport>` and exposes two methods: `__init__(device, num_qps)` for device setup and `transfer_kv(tensor, layer_id)` for KV cache transfers. The `transfer_kv` method classifies the tensor via the lock-free WFA, then enqueues the raw pointer and length into the appropriate SPSC ring—crossing from Python into Rust with a single PyO3 boundary crossing

and no data copy. This replaces the current `vllm_connector.py` (30 lines) which uses pyverbs `MR` allocation on every transfer.

Zero-copy boundary crossing. The PyO3 boundary crossing is a critical efficiency advantage over pure-Python RDMA. When vLLM calls `transfer_kv(tensor, layer_id)`, PyO3 extracts the raw pointer and length from the PyTorch tensor's underlying `data_ptr()` without copying the tensor data. The entire Python→Rust transition costs ∼200 ns (function dispatch, GIL release, argument marshaling). By contrast, the Python-only path requires: pyverbs `MR()` construction (∼100 μs kernel call), copying the tensor metadata into a Python `ibv_send_wr` object (∼1 μs of dict/object creation), and posting via pyverbs (∼10 μs). The Rust path is 500× faster end-to-end because it writes a 64-byte slot into the pre-allocated SPSC ring (L1-resident, ∼50 ns), with the actual RDMA post happening asynchronously on the consumer thread. The tensor data itself is never copied—the RDMA NIC reads directly from the original PyTorch buffer via the pre-registered memory region.

6 Build System

The project is organized as a Rust Cargo workspace with six crates and one C++ component:

Table 3: Workspace crate organization

Crate	Language	Purpose
`rdma-verbs`	Rust	libibverbs/librdmacm FFI with safe wrappers
`spsc-ring`	Rust	Cache-line-aligned SPSC ring buffer
`wfa-classifier`	Rust	Lock-free WFA tensor classifier (DashMap)
`dual-path-router`	Rust	Hot/cold QP routing with MPSC cold queue
`transport-bridge`	Rust	UCX and OpenMPI integration layer
`pyo3-bridge`	Rust	Python bindings for vLLM (PyO3)
`nccl-plugin`	C++	NCCL collective transport plugin

The workspace also includes loom-based concurrency tests for verifying lock-free correctness under all thread interleavings, and Criterion benchmarks for SPSC throughput and raw verbs latency measurement.

Key dependencies. System libraries: `libibverbs-dev` and `librdmacm-dev` (RDMA C FFI targets). Rust crates: `crossbeam` [3] (MPSC cold-path queue), `dashmap` [1] (concurrent hash map for WFA state), `loom` [9] (deterministic concurrency testing), `criterion` (microbenchmarks), and `pyo3` [8] (Python bindings). UCX v1.17.0 is pre-installed on both cluster nodes at `/usr/local/ucx`.

7 Performance Targets

Table 4: Performance targets: Python middleware vs. Rust lock-free

Metric	Python (current)	Rust (target)	Why
CQ poll latency	>1 ms	<1 μs	Busy-poll, no GIL
WFA classify	~10 μs	<100 ns	DashMap + atomic counter
SPSC enqueue	N/A (list append)	<50 ns	Cache-line-aligned, no lock
MR suballocation	~100 μs (syscall)	<10 ns	Slab, pre-registered
Batch flush (8 WRs)	~1 ms	<5 μs	Chained WR list

8 Ring Buffer Design: Lessons from Practice

The HN discussion on ring buffer optimization [6] highlights several design tradeoffs relevant to our SPSC RDMA bridge:

8.1 LMAX Disruptor Pattern

The Disruptor achieves 500M ops/sec by using a single sequence counter (monotonically increasing `u64`) masked with `capacity - 1` for indexing. We adopt this design: the buffer capacity is always a power of two, and indices never wrap—only the mask is applied at access time. This eliminates branch misprediction from wraparound checks.

8.2 Cached Index Optimization

The key insight from the Disruptor (and confirmed in the HN discussion) is that the producer should cache the consumer's tail locally. Instead of reading the consumer's `tail` (on a different cache line) on every enqueue, the producer reads it once and caches the value. It only re-reads when the cache indicates the buffer is full. For a buffer of size N, this reduces cross-cache-line traffic from $O(n)$ to $O(n/N)$ amortized.

8.3 BBQ: Block-Based Queue

The BBQ paper [5] demonstrates that block-based approaches (transferring B elements at once) outperform element-at-a-time designs including Disruptor, especially under contention. Since RDMA transfers are inherently batched (multiple SGEs per WR, multiple WRs per post), BBQ's block transfer maps naturally to our use case.

8.4 MPMC Ring Buffer: Per-Thread Position Tracking

Krizhanovsky [7] presents a lock-free MPMC (Multi-Producer/Multi-Consumer) queue built on a ring buffer that avoids CAS loops entirely, achieving 3.7× speedup over a futex-based locked

implementation on 16-core Xeon hardware (16 producers, 16 consumers).

Slot reservation via `fetch_and_add`. Rather than CAS-based contention on a shared head pointer, each producer atomically reserves a slot using `__sync_fetch_and_add(&head_, 1)`. This single locked instruction both advances the global position and returns the caller's reserved index. The implicit memory barrier from the x86 `LOCK` prefix eliminates the need for explicit fences—a significant advantage on x86 where stores are already ordered with respect to other stores.

Per-thread progress tracking. Each thread maintains a `ThrPos` struct with volatile `head` and `tail` fields, stored in a thread-indexed array. During a push operation, a producer first reserves its slot via `fetch_and_add`, then spins (yielding via `sched_yield`) until the reserved position is within the queue's capacity window. After writing the element into the ring buffer at the masked index, the thread writes `ULONG_MAX` to its position entry, signaling that it is no longer blocking progress. Other threads scan the per-thread position array to determine the minimum in-flight position; any thread still holding a non-`ULONG_MAX` value represents a potential stall point.

Deliberate staleness in `last_head_`/`last_tail_`. The design deliberately avoids CAS on the shared `last_tail_` and `last_head_` trackers. Multiple threads may write potentially stale (smaller) values concurrently. The worst case is a spurious `sched_yield()` when a stale value makes the queue appear full—a benign performance cost compared to the overhead of CAS retry loops. This "optimistic staleness" pattern is directly applicable to our cold-path MPSC queue, where occasional unnecessary yields are preferable to CAS contention.

Relevance to RDMA middleware. Our Phase 3 cold-path MPSC queue borrows two ideas from this design:

1. **Fetch-and-add reservation** instead of CAS contention for the shared write position, reducing coherence traffic under multi-producer workloads.
2. **Per-thread progress arrays** for monitoring in-flight operations, enabling the batch-flush thread to determine when all pending cold-path work requests have been enqueued before issuing `ibv_post_send`.

9 Existing Prototype Validation

An initial SPSC RDMA bridge prototype exists as a compiled binary demonstrating the concept of cache-line-aligned ring buffer communication between RDMA completion threads and application threads. The Python middleware prototypes (five modules totaling ∼190 lines) validated the WFA classification, dual-path routing, and transport selection architecture. The migration path is incremental: the Rust library exposes the same Python API via PyO3, allowing the vLLM integration layer to remain in Python while the hot path executes in Rust.

10 Conclusions

1. The Python middleware validated the WFA/dual-path/transport-selector architecture but introduces unacceptable latency from the GIL, heap allocation, and 1 ms poll intervals.
2. The Neumann codebase provides battle-tested lock-free Rust patterns (CAS loops, atomic counters, loom testing, DashMap sharding) that transfer directly to RDMA transport.
3. The SPSC ring buffer—cache-line-padded, Disruptor-inspired, with cached indices—is the correct data structure for the RDMA hot path, achieving sub-50 ns enqueue latency.
4. The migration is incremental: PyO3 bridges allow the Python API surface (vLLM connector) to remain stable while the hot path moves to Rust.
5. OpenMPI and UCX integration at the C-ABI level enables the middleware to participate in standard HPC collective operations while maintaining lock-free tensor routing.
